Osteosarcoma of the Larynx
Zohreh Sanaat MD*, Ghodrat Mohammady MD**, Heidar Esmaili MD***, Mahmoud Emrani MD†, Roya Dolatkhah MD*

Malignant mesenchymal tumors of the larynx constitute 0.3% to 1% of all laryngeal cancers. Of them, osteosarcoma is the rarest. Osteosarcoma of the larynx may be a difficult clinical diagnosis. Pathologic confirmation of osteoid is required for the diagnosis. Treatment is primarily surgical. It is believed that aggressive surgical intervention directed at complete tumor extirpation is the treatment of choice. Outcomes of such patients are generally poor. Most patients die because of pulmonary metastasis. A case is reported here and a review of all available published cases of osteosarcoma of the larynx is presented.

Keywords: Laryngeal cancer • osteosarcoma

Introduction

Sarcoma constitutes fewer than 1% of the head and neck cancers, and represents fewer than 1% of laryngeal cancers.1,2 Osteosarcoma of the larynx is rare. Pseudosarcoma or carcinosarcoma of the larynx refers to a rare neoplasm containing malignant mesenchymal and epithelial elements. Some researchers have interpreted these tumors as anaplastic carcinoma with pseudosarcoma reactions of the mesenchymal tissue. Experiences with osteosarcoma of the larynx are limited to 15 cases in the literature.1–3 Herein, we report another case of osteosarcoma of the larynx.

Case Report

A 71-year-old man was evaluated for increasing hoarseness for eight months, and dysphagia, odynophagia, and dyspnea since nearly one year ago. He had no weight loss, otalgia, hemoptysis, or constitutional signs of any diseases. He had the history of smoking 30 pack year with no alcohol usage. He had no hypertension or other diseases.

Physical examination revealed bilateral true vocal cords mass with extension to supraglottic region. True vocal cords were fixed. No masses were palpable in his neck. Results of laboratory studies were normal. A computed tomography (CT) scan showed a solid mass, which destructed the true and false vocal cords and extended to supra- and infraglottis areas with no effect on thyroid cartilage (Figure 1).

Total laryngoscopy was done and a biopsy sample was taken from the laryngeal mass and then the total laryngectomy was performed.

Pathology

Microscopic examination of the initial biopsy specimen revealed a malignant tumor with pleomorphic cells, having hyperchromatic, sometimes spindle-shaped nuclei with differential diagnosis of spindle-shaped squamous cell carcinoma and sarcoma. Total laryngectomy specimen revealed the same histologic features of the previous biopsy, but osteoid and woven bone formation was observed in different parts. So, the diagnosis of osteogenic sarcoma was confirmed (Figure 2). After operation, the patient did not

accept any treatment modalities. Eight months later, a bone scan revealed multiple osseous metastases and CT of the chest showed pulmonary metastases. The patient died one year after the diagnosis due to the bone and pulmonary metastases.

Discussion

Osteosarcoma of the larynx was first described in 1942. Malignant sarcoma of the larynx is a rare entity, making up 0.5% to 1% of laryngeal neoplasms. To date, 15 cases of osteosarcoma of the larynx have been described. Of them, 13 patients were males and two were females.2 The most common laryngeal sarcomas are chondrosarcoma and fibrosarcoma. Chondrosarcomas arise most frequently from the cricoid (75%) and thyroid cartilages. Because of their well-differentiated nature, the prognosis is often favorable. Metastatic and poorly-differentiated tumors are rare. Fibrosarcomas of the larynx usually arise from the anterior vocal fold and anterior commeasure. The prognosis depends on the tumor size. The five-year survival rates of well-differentiated and poorly-differentiated tumors are 50% and 5%, respectively.1 Osteosarcoma has also been reported to be metastatic to the larynx, but only primary original osteosarcoma in the larynx is reviewed.

In two of these cases, osteosarcoma occurred by radiation therapy for the head and neck primary tumors.2,13 The etiology of osteosarcoma of the larynx is unknown. There is no direct correlation with alcohol and tobacco use, but this information was only available in a small number of reported cases.3 Our patient used tobacco but did not use alcohol and was not exposed to prior radiation therapy.

The most common presenting complaints in osteosarcoma of the larynx are hoarseness, dyspnea, and acute airway obstruction. In our patient, the mean duration of symptoms was approximately six months before the diagnosis. A summary of the 15 reported cases of primary osteosarcoma and our case is shown in Table 1.1–15

Treatment of osteosarcoma is surgery, radiation therapy, and chemotherapy. The Cooperative Osteosarcoma Study (COSS) group attempted to study the role of various chemotherapeutic regimens on the long-term survival and disease-free-interval in patients with skeletal osteosarcoma.2 Because skeletal osteosarcoma is far more common, much more information should be available for better further improvement.
The COSS group found confirmed data from controlled studies comparing adjuvant versus neoadjuvant chemotherapy. The regimen recommended by the COSS group include methotrexate, doxorubicin, and cisplatin. Because of rarity of osteosarcoma, there are no systematic studies that can prove what kinds of treatments are effective on survival. Most patients died soon after their initial diagnoses, mostly of pulmonary metastasis or local/regional recurrence and bone metastasis. Three of the previous 15 patients were treated with primary radiation therapy. Six
