Percutaneous Intervention

Right Ventricular Function

► Implication for health policy/practice/research/medical education:

To date, the impact of the percutaneous intervention on left ventricular function has been widely studied, with little interest in the right ventricle. This article highlights the importance of the interdependence of the right and left ventricles and the role of percutaneous coronary intervention in the right ventricular function with regard to different lesion sites after isolated right coronary angioplasty.

Percutaneous Coronary Intervention (PCI) has been an integral part of management of coronary artery disease over the past three decades. PCI reduces mortality in ST-segment Elevation Myocardial Infarction (STEMI) and improves cardiovascular outcomes in non-STEMI and unstable angina (1, 2). However, the role of PCI in management of stable coronary artery disease is still debatable (3).

Although determined by interaction of a large number of factors, prognosis of patients with myocardial infarction is directly related to Left Ventricular (LV) function and size (4). In clinical practice, the right ventricle has remained a forgotten chamber behind the left ventricle. Likewise, most studies have evaluated the prognostic importance of LV function with little interest in the right ventricle. However, involvement of the right ventricle was significantly associated with increased mortality in patients with acute STEMI treated with primary PCI (5).

The study by Nikdoust et al. (6) in a recent issue of the

International Cardiovascular Research Journal highlights a significant improvement in Right Ventricular (RV) function, but not LV function, after Right Coronary Artery (RCA) PCI in patients with unstable angina. Echocardiographic measurements were performed in a total of 30 subjects prior to elective PCI. Two months after PCI, echocardiography was repeated and the results were compared to baseline. According to the findings, RV systolic and diastolic functional parameters were significantly improved, but there was no significant correlation between these parameters and LV function. Thus, the authors suggested that revascularization of the RCA might be beneficial for patients suffering from RV failure due to ischemia.

The significant improvement in RV, but not LV, function, after right coronary PCI in a relatively small population is interesting. In agreement with this study, previous studies also reported significant improvements in RV function after PCI. However, these studies mainly included STEMI patients with different locations (5). In a study on 133 patients with inferior infarction without concomitant RV infarction who underwent primary PCI, only regional RV

diastolic dysfunction was observed, whereas alteration of global RV function was more pronounced in patients with anterior wall infarction (7). This study also provided an additional information with the inclusion of unstable angina patients who were referred for isolated RCA PCI.

The right ventricle is different from the left ventricle with respect to many anatomic and physiologic aspects, but they are not independent from each other. The size, shape, and compliance of one ventricle affect the hemodynamic properties of the other, which is called ventricular interdependence (8). As a part of the right ventricle, the interventricular septum is affected more by the left ventricle than by the right ventricle, except in advanced RV dysfunction or severe pulmonary hypertension. Furthermore, inclusion of the interventricular septum in assessment of global RV function is challenging (9).

In 85% of world's population, two-thirds of the right ventricle is supplied by the RCA, whereby RCA gives rise to the posterior descending artery, posterolateral artery, and atrioventricular nodal artery; i.e., right dominant. The inferior wall of the right ventricle is the most susceptible segment to ischemia, while the infundibulum and anterior wall are the most resistant. The elaborate collateral circulation of the right ventricle can protect it against ischemia in case of proximal RCA occlusion (8). Because the severity of RV dysfunction depends on the location of RCA occlusion, information about the lesion sites, collateral vessels, and dominance or codominance would be useful.

RV systolic and diastolic functions can be measured by various echocardiographic parameters, including Right Ventricular Fractional Area Change (RVFAC), Tricuspid Annular Plan Systolic Excursion (TAPSE), Tissue Doppler Imaging (TDI), and Myocardial Performance Index (MPI). All these parameters have many inherent limitations. For instance, RVFAC is experience-dependent with poor reproducibility. In addition, TAPSE may not fully reflect RV contractility as it does not take segmental RV function into account (10). Previous studies have reported that subtle but clinically relevant decreases in ventricular function can be detected using strain (8, 11). Chang et al. (12) also disclosed that in comparison to other traditional echocardiographic parameters of RV assessment, RV free wall longitudinal strain was better for detection of chronic RCA disease.

In contrast to this study, Moller et al. (13) investigated the serial changes of RV function after acute myocardial infarction and found that RV MPI was significantly correlated to LV MPI and this was presumed to be related to ventricular interdependence as mentioned above. In the GISSI-3 Echo substudy, TAPSE was significantly associated with Left Ventricular Ejection Fraction (LVEF) and as LVEF recovered over time, RV function improvement was also observed (14).

In conclusion, it is not clear whether recognition of RV dysfunction in patients with unstable angina will alter our management strategies, such as PCI, and/or medical treatment. Nonetheless, more precise characterization of RV function is warranted to improve our understanding of pathophysiological changes in the right ventricle after reperfusion of a single vessel disease with involvement of the RCA.
