Cardiopulmonary resuscitation (CPR)
Mild hypothermia therapy
Glutathione (GSH)

ABSTRACT

Objective(s): The aim of this study was to investigate the effects of mild hypothermia therapy on oxidative stress injury of rabbit brain tissue after cardiopulmonary resuscitation (CPR).

Materials and Methods: Rabbit models of cardiac arrest were established. After the restoration of spontaneous circulation, 50 rabbits were randomly divided into normothermia and hypothermia groups. The following five time points were selected: before CPR, immediately after CPR, 2 hr after CPR (hypothermia group reached the target temperature), 14 hr after CPR (hypothermia group before rewarming), and 24 hr after CPR (hypothermia group recovered to normal temperature). Glutathione (GSH) concentrations in both the blood and cerebrospinal fluid of the normothermia and hypothermia groups were measured.

Results: At 2, 14, and 24 hr after CPR, the GSH concentrations in both the blood and cerebrospinal fluid were significantly higher in the hypothermia group than in the normothermia group.

Conclusion: Mild hypothermia therapy may increase GSH concentrations in rabbit blood and cerebrospinal fluid after CPR as well as promote the recovery of cerebral function.

Introduction

With the popularity of cardiopulmonary resuscitation (CPR) techniques and the improvement of emergency systems, increasingly more patients are receiving early relief after cardiac arrest. However, 80% of survivors after CPR enter a comatose state (either long- or short-term), 40% enter a persistent vegetative state, and 80% die within 1 year (1). Therefore, cerebral resuscitation is the key to successful CPR.

Oxidative stress is one of the main mechanisms of secondary brain injury after CPR. In the cerebral ischemia period, especially the ischemia-reperfusion period, the formation of oxygen radical increases while the activity of the tissue antioxidant enzyme system that scavenges free radicals decreases; therefore, the levels of antioxidants, represented by glutathione (GSH), reduced. This results in the disruption of the interactions between the oxygen free radicals and antioxidants, which further worsens the cerebral injury (2). Studies indicated that mild hypothermia therapy could inhibit the release of free radicals, reduce reperfusion injury, and decrease neuronal apoptosis (3). In this study, GSH levels in rabbit blood and cerebrospinal fluid of

hypothermia and normothermia groups after CPR were compared to study the effect of mild hypothermia on oxidative stress and brain protection mechanisms (4-6).

Materials and Methods

Experimental animals and groups

Ordinary adult male New Zealand rabbits with an average weight of 2 kg were purchased from the Experimental Animal Center of Medical Sciences, Zhejiang Province (the license number of experimental animals was SYXK [Zhejiang] 2010-0149). After the restoration of spontaneous circulation (ROSC) from cardiac arrest, 50 rabbits were randomly divided into the normothermia and hypothermia groups according to odd and even numbers. Rabbits after ROSC from cardiac arrest in the hypothermia group were first treated with mild hypothermia therapy, while those in the normothermia group were not. After that point, both groups received the same treatment. This study was carried out in strict accordance with the recommendations in the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health. The animal use protocol has been reviewed

and approved by the Institutional Animal Care and Use Committee (IACUC) of XXX.

Rabbit models of cardiac arrest

As published elsewhere (7, 8), the rabbits were kept fast for 18 hr before surgery, with only water consumption. The rabbits were anesthetized via an ear vein injection of sodium pentobarbital (Guangdong Bangmin Pharmaceutical Co., Ltd., Jiangmin, China) (30 mg/kg), fixed, and subjected to electrocardiography (ECG), tracheotomy, and tracheostomy for the insertion of an indwelling tube (Teleflex Medical, Research Triangle Park, US) to maintain indoor spontaneous breathing. The right femoral artery was catheterized and heparinized, and an invasive blood pressure monitoring tube (Argon Critical Care Systems Singapore Pte Ltd. Singapore) and a pressure transducer (Argon Critical Care Systems Singapore Pte Ltd) were used to determine the mean arterial pressure (MAP) and arterial blood gas. The catheter in the right internal jugular vein went in the opposite direction to reach the retrograde venous bulb for measuring the jugular bulb oxygen saturation (SjvO₂). The catheter in the left femoral vein was used for intravenous infusion and administration. The cerebrospinal fluid was collected via cisterna magna puncturing, and 0.3 ml of cerebrospinal fluid was collected from each rat, diluted by 10 times the volume, and then centrifuged to measure the GSH concentration.

We observed and recorded the heart rate and respiration over 5 min, noted the MAP and ECG findings before the experiment, and detected SjvO₂. An arterial blood gas analysis was performed to detect normal blood and cerebrospinal fluid GSH concentrations. Tracheal tube occlusion was performed to induce oxygen-deficient cardiac arrest in the end-expiratory phase (cardiac arrest indicators: 0 for MAP; ventricular fibrillation, electromechanical dissociation, and a straight line on an ECG report). The clip was then released on the closed trachea 5 min after cardiac arrest, and the rabbits were immediately resuscitated, placed on a ventilator (The Medical Instrument of Zhejiang University, Hangzhou, China), administered epinephrine (Yokon, Beijing, China) intravenously, and given chest compressions—to reach the ROSC standard aortic systolic pressure of ≥ 6.67 kPa—that was continued for 1 min (9). The successful recovery models were included in the study groups, while the unsuccessful recovery models were excluded.

The 50 rabbits after the ROSC from cardiac arrest were randomly divided into the normothermia and hypothermia groups according to odd and even numbers. Continuous treatment was given using intravenous propofol (AstraZeneca, London, UK) as a sedative and vecuronium bromide (Ojiaonong, Nanjing, China) as a muscle relaxant. After ROSC

from cardiac arrest, the rabbits in the hypothermia group were treated with mild hypothermia therapy (10) consisting of saline at 4°C, cooling blankets, ice caps, and ice packs placed on the head and large blood vessels in the shallow areas for cooling to reach the target temperature (controlled rectal temperature at 32 to 4°C) within 2 hr. We then maintained the target temperature for 12 hr by rewarming at increasing temperatures of 0.3 to 0.5°C per hr. When the rabbit was back to normal body temperature (39 to 39.5°C) after about 10 hr, we stopped using the muscle relaxant to prevent the occurrence of reactive fever after rewarming (11,12). The normothermia group was given the same treatment without the hypothermia component.

Index detection

We continuously performed ECG monitoring and MAP and recorded the ECG changes before and after endotracheal tube clipping, the cardiac arrest time, ROSC situation, and the time when the target temperature was reached in the hypothermia group.

Monitoring indicators before CPR were taken as normal control values. Another four time points were set: 0, 2, 14, and 24 hr after CPR. SjvO₂ and arterial blood gas analysis in the normothermia and hypothermia groups were observed. An enzyme-linked immunosorbent assay was used to detect GSH in the blood and cerebrospinal fluid. The measurements were carried out in accordance to the GSH kit instructions (lot E90294Ge; USCN Life Science Inc., Wuhan, China).

At 72 hr after CPR, the rabbits were divided into the following five groups according to cerebral nerve function criteria: 1 point, normal daily activities and sensitive environmental stimuli response; 2 points, mild impairment of daily activities, unresponsive to environmental stimuli; 3 points, severe impairment of daily activities, conscious but unresponsive to environmental stimuli; 4 points, coma; and 5 points, death. In short, 1 to 3 points indicated a good prognosis, while 4 and 5 points indicated a poor prognosis (13).

Statistical analysis

SPSS13.0 software was used for the data analysis. Normally distributed data were expressed as mean \pm standard deviation, while a *t*-test was used to identify differences between the groups, and the chi-square test was used to assess prognosis. Values of *P* < 0.05 were considered to statistically significant.

Results

Physiological indicators

The physiological indicators including MAP, SjvO₂, PaO₂, PaCO₂, and pH of the rabbits blood before cardiac arrest in the two groups were not significantly different. The indicators at the other

four time points (0, 2, 14, and 24 hr after CPR) in the two groups are shown in Table 1.

Blood GSH levels

The blood GSH levels were significantly higher in the hypothermia group than in the normothermia group at 2, 14, and 24 hr after CPR ($P < 0.05$, Figure 1).

Cerebrospinal fluid GSH levels

The cerebrospinal GSH levels were significantly higher in the hypothermia group than in the normothermia group at 2, 14, and 24 hr after CPR ($P < 0.05$, Figure 2).

Prognostic classification of cerebral function

At 72 hr after CPR, the prognostic classification of rabbit cerebral function in the hypothermia group was significantly better than that in the normothermia group ($P < 0.05$), as determined by using the chi-square test (Table 2).

Discussion

After cardiac arrest, the body's blood circulation almost stops and the body organs and tissues enter an extremely serious condition of ischemia and hypoxia. After effective and timely CPR, systemic blood flow is restored, but the body faces a new challenge i.e. reperfusion injury (14, 15). A large amount of oxygen free radicals are formed and cause tissue macromolecule peroxide damages, resulting in large amounts of methane dicarboxylic aldehyde and other degradation products of peroxidation that damage cell membranes, cause structural and functional changes in the mitochondria and endoplasmic reticulum, and increase cellular energy metabolism, which creates a vicious cycle and ultimately leads to neuronal apoptosis and necrosis (16). The cerebral blood supply becomes rich, oxygen consumption increases, and xanthine oxidase enzyme levels increase; thus, ischemia-reperfusion injury to the brain tissue has an extremely serious

impact. Studies have shown that oxidative stress is one of the main mechanisms of secondary brain injury after CPR (17, 18).

The intracellular antioxidant barrier consists of the following two systems: the antioxidant enzyme systems represented by superoxide dismutase and the cell small molecule antioxidants represented by GSH; both these systems are related and coordinated under normal circumstances, and they maintain a stable intracellular environment (19, 20). GSH peroxidase is an important peroxide enzyme present

throughout the body. As an important part of GSH, the mercapto group in cysteine combines with radicals to clear peroxide metabolites and breaks the lipid peroxidation chain reaction. It also protects cell membrane structure and function integrity as well as brain cells from damage, making it an important deoxidizer in the body. The protective effects could be divided into early and late stages. Early protection appeared a few minutes after administration, lasted for 2 to 3 hr, and was mainly related to the active substance and the endogenous active substances. The late stage occurred 24 hr after administration, lasted for several days, and was mainly related with gene expression enhancement and inhibition of proteins such as heat shock protein, brain-derived neurotrophic factor, cytokines, and antioxidant enzymes (21). Under normal circumstances, in the cerebral ischemia period after CPR, particularly the ischemic-reperfusion period, oxygen radical formation increased, while the activity of the tissue antioxidant enzyme system, which can scavenge the free radicals, decreased in order to reduce antioxidants (represented by GSH levels), then disrupted the intergroup balance, resulting in further worsening of brain damage (22, 23). However, as the disease improved, its content rebounded. The study found that GSH levels in the blood and cerebrospinal fluid in the ischemia-reperfusion period after CPR significantly decreased, which confirmed the findings of the reports mentioned above.

Mild hypothermia therapy has already been widely used in clinical studies, but its use after CPR has been seldom reported. After cardiac arrest, free radicals and a large variety of inflammatory factors are produced, calcium overload occurs, excitatory amino acids are released, and persistent and severe inflammation is induced, followed by cell damage and death (24). Studies have indicated that mild hypothermia therapy can inhibit the release of free radicals, decrease the release of inflammatory cytokines (25-27) and calcium ions, improve the ion pump function, and decrease reperfusion injury (28, 29). Hypothermia could also decrease the brain metabolic rate (30-32), maintain the integrity of blood-brain barrier, inhibit the expression of aquaporin-4, and ease cerebral edema by reducing vascular permeability (33, 34). Another study reported that hypothermia can significantly decrease the release of glutamate and dopamine and inhibit protein kinase C and nitric oxide synthase, inhibit the release of excitatory amino acids, decrease the

degree of brain damage and neuronal death (35), promote the production of the brain anti-apoptotic B-cell lymphoma-2 protein after cardiac arrest, inhibit the expression of pro-apoptotic factor Bax (36), and prevent apoptosis in the early stages of brain injury. This study found that GSH levels in rabbit blood and cerebrospinal fluid after CPR were significantly higher in the hypothermia group than in the normothermia group, and the prognosis was significantly better in the former group, suggesting that hypothermia can reduce oxidative stress injury and neuronal apoptosis.

Conclusion

After CPR, GSH levels in rabbit blood and cerebrospinal fluid were significantly higher in the hypothermia group than in the normothermia group. In addition, the prognosis of the rabbits was significantly better in the former group. These findings show that mild hypothermia therapy can inhibit the release of oxygen free radicals and relieve reperfusion injury and neuronal death. This work provides a theoretical foundation for the use of mild hypothermia in the prevention of secondary brain injury after CPR.
