Abstract:

The study area is situated in the Cenozoic central Iranian magmatism belt, in Southwest of Nain. The Eocene country rocks covering a vast area are predominantly volcanic and pyroclastic. These rocks are acid to intermediate in composition and range from pyroxene- andesite through trachy-andesite to trachy- dacite. The country rocks have been subjected to trachy- alterations including silicification, sericitization, chloritization, kaolinitization and particularly alunitization. The latter alteration is widespread and due to its importance for mercury, silver and gold mineralization a major part of the study has been focused on it.

The altered volcanic rocks consist mainly of alunite, natro- alunite, jarosite a well as barite, pyrite, hematite and microcrystalline quartz. The geochemical study of altered rocks was carried out by using NAA and XRD methods. The obtained data indicated that the studied rocks are enriched in silver, mercury and gold and an epithermal model may be proposed for the hydrothermal alteration of the study area.

Keywords: Alteration, Volcanic Rocks, Alunite, Epithermal ore deposit, Central Iran Magmatism, Nain

A satellite image showing a volcanic landscape. A large, irregular lava flow dominates the center-left, characterized by a mix of reddish-brown and dark grey colors. The surrounding terrain is a mix of green and brown, indicating different rock types or vegetation. In the bottom left corner, the words "Altered Volcanic" are written in a white, sans-serif font. The entire image is covered by a large, semi-transparent watermark that reads "Archive of SID" diagonally from the bottom left to the top right.
